# Equilibrium Analyses of Market-driven Agents 

KWANG MONG SIM<br>Department of Information Engineering, Chinese University of Hong Kong, Shatin, NT, Hong Kong. Email: kmsim@ie.cuhk.edu.hk

Market-driven agents (MDAs) are negotiation agents that make adjustable amounts of concession by considering factors such as competition, deadlines, and trading options. While previous work demonstrates the properties of MDAs by experiments, this paper provides mathematical analyses to show that (1) for a given market situation, an MDA makes minimally sufficient concession, and (2) the strategies adopted by MDAs are in equilibrium. The results show that $M D A s$ are stable (stability is an essential evaluation criterion for negotiation agents) and they avoid making excessive or inadequate concession in a market situation.

Additional Key Words and Phrases: e-Negotiation, Market-driven Agent, Sequential Equilibrium.

## 1. INTRODUCTION

Although there are many extant negotiation agents designed for e-commerce ([1,2], just to name a few because of space limitation), strategies adopted by these agents do not take the dynamics of the market into consideration. This paper presents a market-driven model [3] for designing negotiation agents (section 2), and proves that for a given market situation, a market-driven agent ( $M D A$ ) does not over-compromise or under-compromise (section 3) and the strategies adopted by MDAs are stable (section 4). In dynamic markets where products/services become available, and traders enter and leave a market, the condition for deliberation changes as new opportunities and threats are constantly being introduced. Additionally, negotiation is also bounded by time, since deadline puts negotiators under pressure [4]. Previous empirical results [5] show that in general, MDAs [3,5,6] outperform fixed strategy negotiation agents [1] in many situations. In [4], a more flexible negotiation model defines a range of strategies and tactics for generating (counter-)proposals based on time, resource and behaviors of negotiators. The major difference between this work and [4] is that other essential factors such as competition, trading alternatives and differences among negotiators' proposal are also considered. In multilateral negotiations, it is intuitive to think that a negotiator's bargaining power is affected by the number of competitors and trading alternatives. Good options give a negotiator more "power" because the negotiating party needs not pursue the negotiation with any sense of desperation [7, p157], and negotiations may break down because the parties cannot resolve their differences [8, p94]. However, this work does not compete with [1], [4] or the current literature, but rather complements them by modeling the behaviors of negotiation agents in changing market situations. In designing MDAs [5,6], factors such as competition, trading alternatives, differences among negotiators and deadline are taken into account when an agent determines the amount of concession at each negotiation round (section 2).

[^0]
## 2. A MARKET-DRIVEN MODEL FOR DESIGNING NEGOTIATION AGENTS

In making concession, an $M D A$ assesses the probability $p$ of successfully completing a deal in different market situations. One way to assess $p$ is to consider the value of $k-$ the spread (difference) between an agent's bid/offer and that of others [3]. Let $v^{a \rightarrow j}{ }_{i}$ be the utility of an agent and $w^{j \rightarrow a}{ }_{i}$ be the best utility among all its trading partners in the current trading cycle. The (best) spread in the current cycle $i$ is $k_{i}=v^{a \rightarrow j}{ }_{i}-w^{j \rightarrow a}{ }_{i}$. A market-driven agent makes concession by determining the utility of its next bid/offer $v^{a \rightarrow j}{ }_{i+1}$ using the sum of the spread in the next cycle $k_{i+1}$ and $w^{j \rightarrow a}{ }_{i}$. Hence, $v^{a \rightarrow j_{i+1}}=k_{i+1}+w^{j \rightarrow a}{ }_{i}$. An agent strives to attain the highest possible utility while maintaining a reasonable level of $p$ in the next trading cycle. It is more probable to complete a deal when $k_{i+1}$ is small, and vice versa. $k_{i+1}$ is determined by assessing the current market situation, taking into account factors such as opportunity, competition and deadline:

$$
\begin{equation*}
k_{i+1}=\left[O\left(n^{a}{ }_{i},<w^{j \rightarrow a}{ }_{i}>, v^{a \rightarrow j}{ }_{i}\right) C\left(m^{a}{ }_{i}, n^{a}{ }_{j}\right) T(t, \tau, \varepsilon)\right] k_{i} \tag{1}
\end{equation*}
$$

Trading opportunity: $O\left(n^{a}{ }_{i},\left\langle w^{j \rightarrow a}{ }_{i}>, v^{a \rightarrow j}{ }_{i}\right)\right.$ determines the amount of concession based on trading alternatives (number of trading partners) and differences in offers/bids [3,6]. Suppose agent $\boldsymbol{a}$ engages $j$ in round $i$. $\boldsymbol{a}$ 's last proposal generates a payoff of $v^{a \rightarrow j}{ }_{i}$ for itself, and $j$ 's last counter-proposal generates a payoff of $w^{j \rightarrow a}{ }_{i}$ for $\boldsymbol{a}$. If $\boldsymbol{a}$ accepts $j$ 's counter-proposal, it will obtain $w^{j \rightarrow a}{ }_{i}$ with certainty. If $\boldsymbol{a}$ insists on its last proposal, and i) if $j$ accepts it, $\boldsymbol{a}$ will obtain $v^{a \rightarrow j}{ }_{i}$ and ii) if $j$ does not accept it, $\boldsymbol{a}$ may be subjected to a conflict utility $c^{a} . c^{a}$ is the worst possible utility for $\boldsymbol{a}$ (i.e. an agent's payoff in the absent of agreement [9]), hence, $w^{j \rightarrow a}{ }_{i} \geq c^{a}$. If $j$ does not accept $\boldsymbol{a}$ 's last proposal, $\boldsymbol{a}$ may ultimately have to settle with lower utilities (the lowest possible being the conflict utility), if there are changes in the market situation in subsequent cycles. For instance, a may face more competitions in subsequent cycles, and may have to ultimately accept a utility that is lower than $w^{j \rightarrow a}{ }_{i}$ (possibly as low as $c^{a}$ ). If the subjective probability of $\boldsymbol{a}$ obtaining $c^{a}$ is $p^{a \leftrightarrow j}{ }_{c, i}$ (conflict probability) and the probability that $\boldsymbol{a}$ achieves $v^{a \rightarrow j}{ }_{i}$ is $1-p^{a \leftrightarrow j}{ }_{c, i}$, then, according to Zeuthen's analysis [9], if $\boldsymbol{a}$ insists on holding its last proposal, $\boldsymbol{a}$ will obtain a payoff of $\left(1-p^{a \leftrightarrow j}{ }_{c, i}\right) v^{a \rightarrow j}{ }_{i}+p^{a \leftrightarrow j}{ }_{c, i} c^{a}$. Hence, $\boldsymbol{a}$ will find that it is advantageous to insist on its last proposal only if $\left(1-p^{a \leftrightarrow j}{ }_{c, i}\right) v^{a \rightarrow j}{ }_{i}+p^{a \leftrightarrow j}{ }_{c, i} c^{a} \geq w^{j \rightarrow a}{ }_{i}$. Hence, $p_{c, i}^{a \leftrightarrow j} \leq\left(v^{a \rightarrow j}{ }_{i}-w^{j \rightarrow a}{ }_{i}\right) /\left(v^{a \rightarrow j}{ }_{i}-c^{a}\right)$. Consequently, the maximum value of $p_{c, i}^{a \leftrightarrow j}$ is the highest probability of a conflict that $\boldsymbol{a}$ may encounter in round $i$, given as [3,6]:

$$
\begin{equation*}
p^{a \leftrightarrow j}{ }_{c, i}=\left(v^{a \rightarrow j}{ }_{i}-w^{j \rightarrow a}{ }_{i}\right) /\left(v^{a \rightarrow j}{ }_{i}-c^{a}\right) \tag{2}
\end{equation*}
$$

$p^{a \leftrightarrow j}{ }_{c, i}$ is a ratio of difference between two utilities. While $v^{a \rightarrow j}{ }_{i}-w^{j \rightarrow a}{ }_{i}$ measures the cost of accepting the trading agent's last offer (the spread $k$ or difference between the (counter)proposals of $\boldsymbol{a}$ and $j$ ), $v^{a \rightarrow j}{ }_{i}-c^{a}$ measures the cost of provoking a conflict. Hence, the probability that $\boldsymbol{a}$ will obtain a utility $\nu^{a \rightarrow j}{ }_{i}$, with at least one of its $n^{a}{ }_{i}$ trading partners is

$$
\begin{equation*}
O\left(n_{i}^{a},\left\langle w_{i}^{j \rightarrow a}\right\rangle, v_{i}^{a \rightarrow j}\right)=1-\prod_{j=1}^{n_{i}^{a}} \frac{v_{i}^{a \rightarrow j}-w_{i}^{j \rightarrow a}}{\left(v_{i}^{a \rightarrow j}-c^{a}\right)} \tag{3}
\end{equation*}
$$

With ample trading options, $O\left(n_{i}{ }_{i},\left\langle w^{j \rightarrow a}{ }_{i}>, v^{a \rightarrow j}{ }_{i}\right)\right.$ approaches 1 , an MDA has more bargaining power, and hence, makes smaller compromises. Since there are a very large number of trading partners, the likelihood that some other agent's proposals is potentially closer to the MDA's proposal is higher (proven in [3]). As $O\left(n^{a}{ }_{i},\left\langle w^{j \rightarrow a}{ }_{i}>, \nu^{a \rightarrow j}{ }_{i}\right)\right.$ reduces to 0 , an $M D A$ 's bargaining power decreases. It makes larger compromises. Even with a very large number of trading options, it would be difficult for an $M D A$ to reach a consensus if there are large differences between itself and other negotiating parties (proven in [3]).

Competition: $C\left(m_{i}^{a}, n^{a}{ }_{i}\right)$ determines the probability that an agent $\boldsymbol{a}$ is ranked as the most preferred trading partner by at least one other agent in round $i$. If $\boldsymbol{a}$ has $m^{a}{ }_{i}-1$
competitors, and one trading partner, the probability that $\boldsymbol{a}$ is not the most preferred trading partner is $\left(m^{a}{ }_{i}-1\right) / m^{a}{ }_{i}$. If $\boldsymbol{a}$ has $m^{a}{ }_{i}-1$ competitors, and $n^{a}{ }_{i}$ trading partners, the probability that $\boldsymbol{a}$ is not the most preferred partner of all its trading partners is $\left[\left(m_{i}{ }_{i}-1\right) / m^{a}{ }_{i}\right]^{n_{i}}$. Hence, in round $i$, the probability that $\boldsymbol{a}$ is considered the most preferred trading partner by at least one agent is:

$$
\begin{equation*}
C\left(m^{a}{ }_{i}, n^{a}{ }_{i}\right)=1-\left[\left(m_{i}^{a}-1\right) / m_{i}^{a}\right]^{n_{i}} \tag{4}
\end{equation*}
$$

If there is a very large number of trading partners $n^{a}$, then the chances of being considered the most preferred trading partner by some parties is higher. When the number of competitors $m^{a}{ }_{i}$ increases significantly, the likelihood of being considered the most preferred trading partner becomes much lower. These claims were proven in [3].
Deadline: $T(t, \tau, \lambda)$ is a time-dependent function given as:

$$
\begin{equation*}
T(t, \tau, \lambda)=1-(t / \tau)^{\lambda} \tag{5}
\end{equation*}
$$

where $t$ is current trading time, $\tau$ is the deadline, and $\lambda$ is a nonnegative temporal sensitivity factor. At the start of negotiation ( $t=0$ ), an $M D A$ offers its initial price since $T(t, \tau, \lambda)=1-(0 / \tau)^{\lambda}=1$; when its deadline is reached, the $M D A$ offers its reserve (final) price since $T(t, \tau, \lambda)=1-(\tau / \tau)^{\lambda}=0$. Although agents can select from an infinitely many strategies with respect to remaining trading time (one for each value of $\lambda$, where $\lambda \geq 0$ ), they can be classified as follows [3]:

1) Linear: $\lambda=1$ and $T(t, \tau, \varepsilon)=1-(t / \tau)$. An MDA makes a constant rate of concession.
2) Conservative: $k_{i+I}=\left[1-(t / \tau)^{\lambda}\right] k_{i}$ where $\lambda>1$, an MDA makes smaller concession in early rounds and larger concessions in later rounds.
3) Conciliatory: $k_{i+I}=\left[1-(t / \tau)^{\lambda}\right] k_{i}$ where $\lambda<1$, an $M D A$ makes larger concessions in the early trading rounds and smaller concessions at the later stage.
4) The extreme and special cases when $\lambda=0$ (always giving in) and $\lambda=\propto$ (never give in) will not be considered because they represent the situations when no negotiation is needed and non-negotiable trading respectively.
In [10] MDAs are designed with a time-dependent function $T(t, \tau, \varepsilon)=1-(t / \tau)^{1 / \varepsilon}$ that models its degree of sensitivity to approaching deadlines with respect to the MDA's eagerness $\varepsilon . \varepsilon$ represents the user's desire to complete the deal. Given 2 agents $a_{1}$ and $a_{2}$ with the same deadline $\tau_{I}=\tau_{2}$, but different eagerness $\varepsilon_{1}$ and $\varepsilon_{2}$ with $\varepsilon_{1}>\varepsilon_{2}$ then at time $t$, $T\left(t, \tau_{1}, \varepsilon_{1}\right)<T\left(t, \tau_{2}, \varepsilon_{2}\right) ; a_{1}$ having higher eagerness makes more concessions than $a_{2}$. Consequently, $a_{l}$ adopts a strategy that is more likely to complete a deal faster. This corresponds with the intuition that negotiators that are more eager to complete a deal are more likely to concede faster. In [10], MDAs are designed with only conservative (with $0<\varepsilon<1$ ) and linear strategies (with $\varepsilon=1$ ).

## 3. MINIMALLY SUFFICIENT CONCESSION

Given the current market situation, an $M D A$ strives to attain the highest possible utility while maintaining a reasonable probability $p$ of reaching a consensus. However, both increasing an MDA's utility and increasing $p$ are incompatible objectives. One way to deal with incompatible objectives is to determine the most important objective, and express all other objectives as constraints. For MDAs, maximizing utility is the most important objective, but they are also designed to maintain a minimum $p$. This section shows that with respect to opportunity and competition (propositions 1 and 2), the amount of concession made by an $M D A$ is minimally sufficient [11].

Definition 1: A sufficient concession is one that increases a market-driven agent's probability of reaching a consensus.
Definition 2: A concession $\Delta k$ is minimally sufficient if it achieves the highest possible utility for a market-driven agent while maintaining a minimum probability $p_{\min }$ of reaching a consensus.

Proposition 1: With respect to trade opportunity, the amount of concession $\Delta k_{\text {opp }}$ made by a market-driven agent is minimally sufficient.

Proof: The proof proceeds by induction on the number of trading partners $n$.
Base case: When $n=1$. Let $\Delta k_{\text {opp }}$ be the amount of concession made by an MDA. Since $p^{a \leftrightarrow j}{ }_{c, i} \leq\left(v^{a \rightarrow j}{ }_{i}-w^{j \rightarrow a}{ }_{i}\right) /\left(v^{a \rightarrow j}{ }_{i}-c^{a}\right)$ and $p=1-p_{c, i}^{a \leftrightarrow j}$, it follows that $p$ is the minimum probability of reaching a consensus when $p^{a \leftrightarrow j}{ }_{c, i}=\left(v^{a \rightarrow j}{ }_{i}-w^{j \rightarrow a}{ }_{i}\right) /\left(v^{a \rightarrow j}{ }_{i}-c^{a}\right)=k_{i} /\left(v^{a \rightarrow j}{ }_{i}-c^{a}\right)$. When $n=1$, with respect to trade opportunity, $k_{i+1}=O\left(1,\left\langle w^{I \rightarrow a}{ }_{i}>, v^{a \rightarrow l}{ }_{i}\right) k_{i}\right.$ and $\Delta k_{\text {opp }}=k_{i}-k_{i+1}=1-O\left(1,<w^{I \rightarrow a}{ }_{i}>, v^{a \rightarrow l}{ }_{i}\right)=\left(v^{a \rightarrow l} l_{i^{-}}\right.$ $\left.w^{l \rightarrow a}{ }_{i}\right) /\left(v^{a \rightarrow l}{ }_{i}-c^{a}\right)=k_{i}\left(\left(v^{a \rightarrow l}{ }_{i}-c^{a}\right)\right.$.
Inadequate concession: Let $\Delta k_{u}$ be any amount of concession such that $\Delta k_{u}<\Delta k_{\text {opp }}$ and $p_{u}$ be the corresponding probability of reaching a consensus if the $M D A$ concedes with $\Delta k_{u}$. Although $\Delta k_{u}$ generates a higher utility for the $M D A$ because the corresponding spread $k_{u}>k_{i}$, it follows that $k_{u} /\left(v^{a \rightarrow l}{ }_{i}-c^{a}\right)>p^{a \leftrightarrow l}{ }_{c, i}=k_{i} /\left(v^{a \rightarrow l}{ }_{i}-c^{a}\right)$, and $p_{u}<p=p_{\text {min }}$, which contradicts definition 2.
Excessive concession: Let $\Delta k_{o v}$ be any amount of concession such that $\Delta k_{o v}>\Delta k_{o p p}$ and $p_{o v}$ be the corresponding probability of reaching a consensus if the $M D A$ concedes with $\Delta k_{o v}$. Since the corresponding spread $k_{o v}<k_{i}$, it follows that $p_{o v}>p=p_{\text {min }}$. However, $\Delta k_{o v}$ is sufficient (definition 1) but not minimally sufficient because it generates a lower utility for the $M D A$. Hence, $\Delta k_{\text {opp }}$ is minimally sufficient.

Induction case: When $n>1$, assume as an induction hypothesis that an $M D A$ makes minimally sufficient concession when $n<N$. With respect to competition, when $n=N$, it follows that $k_{i+1}=O\left(N,<w^{j \rightarrow a}{ }_{i}>, \nu^{a \rightarrow j}{ }_{i}\right) k_{i}$ and $\Delta k_{\text {opp }}=k_{i}-k_{i+l}=1-O\left(N,<w^{j \rightarrow a}{ }_{i}>, \nu^{a \rightarrow j}{ }_{i}\right)$

$$
=\prod_{j=1}^{N} \frac{v_{i}^{a \rightarrow j}-w_{i}^{j \rightarrow a}}{\left(v_{i}^{a \rightarrow j}-c^{a}\right)}=\frac{k_{i}^{a \rightarrow 1} \times k_{i}^{a \rightarrow 2} \times \ldots \times k_{i}^{a \rightarrow N}}{\left(v_{i}^{a \rightarrow j}-c^{a}\right)^{N}}=\frac{k_{i}^{a \rightarrow 1} \times k_{i}^{a \rightarrow 2} \times \ldots \times k_{i}^{a \rightarrow r-1}}{\left(v_{i}^{a \rightarrow j}-c^{a}\right)^{r-1}} \times \frac{k_{i}^{a \rightarrow r}}{\left(v_{i}^{a \rightarrow r}-c^{a}\right)} \times \frac{k_{i}^{a \rightarrow r+1} \times \ldots \times k_{i}^{a \rightarrow N}}{\left(v_{i}^{a \rightarrow j}-c^{a}\right)^{N-r}} .
$$

 concession that the MDA makes to $r$. Let $\Delta k_{r}=\frac{k_{i}^{a \rightarrow r}}{\left(v_{i}^{a \rightarrow r}-c^{a}\right)}=\frac{v_{i}^{a \rightarrow r}-w_{i}^{r \rightarrow a}}{\left(v_{i}^{a \rightarrow r}-c^{a}\right)}$. By the same argument given above (the base case), $\Delta k_{r}$ is also minimally sufficient. Let $\{1,2, \ldots, r-1, r+1, \ldots, N\}$ be the set of all other trading partners of the MDA other than $r$ and $\Delta k_{N-1}=\frac{k_{i}^{a \rightarrow 1} \times k_{i}^{a \rightarrow 2} \times \ldots \times k_{i}^{a \rightarrow r-1}}{\left(v_{i}^{a \rightarrow j}-c^{a}\right)^{r-1}} \times \frac{k_{i}^{a \rightarrow r+1} \times \ldots \times k_{i}^{a \rightarrow N}}{\left(v_{i}^{a \rightarrow j}-c^{a}\right)^{N-r}}$ such that $\Delta k_{o p p}=\Delta k_{N-l} \times \Delta k_{r}$. By induction hypothesis, $\Delta k_{N-I}$ is minimally sufficient. Since $\Delta k_{N-I}$ and $\Delta k_{r \text {. both }}$ are minimally sufficient, it follows that $\Delta k_{o p p}$ is also minimally sufficient

Proposition 2: With respect to competition in a given market size with $m$ numbers of competitors and $n$ numbers of trading partners, the amount of concession $\Delta k_{\text {com }}$ made by a market-driven agent is minimally sufficient.

Proof: Since market-driven agents are utility maximizing agents, a market-driven agent $B_{l}$ is not likely to reach a consensus with another market-driven agent $S_{i}$ if $B_{l}$ 's proposal is not ranked as the best proposal by $S_{i}$. Suppose $B_{I}$ has $n$ trading partners and $m$ competitors. Let $E_{1}, E_{2}, \ldots, E_{\mathrm{n}-1}, E_{\mathrm{n}}$ be the events that $B_{I}$ 's proposal is not ranked the best proposal by exactly $1,2, \ldots, n-1, n$ other trading partners respectively. The worst case scenario is $E_{\mathrm{n}}$, when $B_{l}$ 's proposal is not ranked the best proposal by all of its $n$ trading partners, in which case, it is most unlikely to reach a consensus with any $S_{i} \in \mathbf{S}$. Let $P_{c}$ be the probability of conflict with respect to competition. $P_{c}$ is the largest possible when $B_{l}$ 's proposal is not ranked as the best proposal by all $S_{i} \in \mathbf{S}$. Let $p$ be the probability of reaching a consensus. Since $p=1-P_{c}$, with respect to competition, $p$ is the smallest possible when $E_{\mathrm{n}}$ occurs. $\Delta k_{\text {com }}=k_{i^{-}} k_{i+1}=1-C\left(m^{a}{ }_{i}, n^{a}{ }_{i}\right)=\left[\left(m^{a}{ }_{i}-1\right) / m^{a}{ }_{i}\right]^{n^{a}}{ }_{i}$ is determined based on the assumption that $E_{\mathrm{n}}$ occurs.
Inadequate-concession: By making a concession $\Delta k_{u}<\Delta k_{\text {com }}$, it will be even less likely that $B_{I}$ 's proposal is ranked the best proposal by some other agent. Consequently, the corresponding probability $p_{u}<p=p_{\text {min }}$ violates definition 2 .
Excessive-concession: Let $\Delta k_{o v}$ be any amount of concession such that $\Delta k_{o v}>\Delta k_{c o m}$ and the corresponding probability of completing the deal be $p_{o v}$. Although $p_{o v}>p=p_{\min }, \Delta k_{o v}$ generates a lower utility for the $M D A$ since the corresponding spread $k_{o v}<k$. Thus, $\Delta k_{o v}$ is sufficient but not minimally sufficient. Hence, $\Delta k_{\text {com }}$ is minimally sufficient .

## 4. SEQUENTIAL EQUILIBRIUM

The amount of concession that an $M D A$ makes with respect to its deadline is $\Delta k_{D L}=1-T(t, \tau, \varepsilon)=(t / \tau)^{1 / \varepsilon}$. Since $\Delta k_{D L}$ is not determined by the number of trading partners, for the purpose of analyzing the time-dependent strategies of MDAs, a multi-lateral negotiation is treated as many threads of one-to-one negotiation. This section shows that (i) when an $M D A$ adopts a conservative strategy, it requires more trading rounds to reach a consensus with its trading partner (lemma 3.1) than using either the conciliatory or linear strategy, (ii) the conservative strategy is the optimal strategy for an MDA regardless of the strategy adopted by its trading partner (lemma 3.2), and (iii) the strategies of MDAs are in equilibrium (proposition 3).

Lemma 3.1: A market-driven agent $\boldsymbol{b}$ adopting a strategy with $\lambda^{b}{ }_{1}>1$ requires more negotiation rounds to reach an agreement than when $\boldsymbol{b}$ adopts a strategy with $\lambda^{b}{ }_{2} \leq 1$ regardless of the strategy $\lambda^{s}$ adopted by its trading partner $\boldsymbol{s}$.

Proof: Let $T_{1}$ (respectively, $T_{2}$ ) be the number of rounds that $\boldsymbol{b}$ adopting a strategy with $\lambda^{b}{ }_{1}>1$ (respectively, $\lambda^{b}{ }_{2} \leq 1$ ) completes a deal with $\boldsymbol{s}$. Let $k_{1, t}$ (respectively, $k_{2, t}$ ) be the spread between $\boldsymbol{b}$ adopting $\lambda^{b}{ }_{1}$ (respectively, $\lambda^{b}{ }_{2}$ ) and $\boldsymbol{s}$ in round $t$. Since market-driven strategies are designed for both buyer and seller agents, it can be assumed without loss of generality that $\boldsymbol{b}$ makes a concession first, hence, at round $t$ it follows that:
$k_{a, t}= \begin{cases}{\left[T\left(1, \tau^{b}, \lambda_{a}^{b}\right) \times T\left(2, \tau^{s}, \lambda^{s}\right) \ldots \times T\left(t, \tau^{s}, \lambda^{s}\right)\right] \times k_{a, 0}} & t \text { is odd } \\ {\left[T\left(1, \tau^{b}, \lambda_{a}^{b}\right) \times T\left(2, \tau^{s}, \lambda^{s}\right) \ldots \times T\left(t, \tau^{b}, \lambda_{a}^{b}\right)\right] \times k_{a, 0}} & t \text { is even }\end{cases}$
where $a=1$ if $\boldsymbol{b}$ adopts $\lambda^{b}{ }_{1}$, otherwise $\boldsymbol{b}$ adopts $\lambda^{b}{ }_{2}$. Consequently, $k_{\mathrm{a}, t}$ can be re-written as:

$$
k_{a, t}= \begin{cases}\prod_{i=0}^{I}\left(\left[1-\left(\frac{2 i+1}{\tau^{b}}\right)^{\lambda_{a}^{b}}\right] \times\left[1-\left(\frac{2 i}{\tau^{s}}\right)^{\lambda^{s}}\right]\right) \times k_{a, 0} & , t=2 I+1 \\ \prod_{i=0}^{I}\left(\left[1-\left(\frac{2 i+1}{\tau^{b}}\right)^{\lambda_{a}^{b}}\right] \times\left[1-\left(\frac{2 i+2}{\tau^{s}}\right)^{\lambda^{s}}\right]\right) \times k_{a, 0} & , t=2 I+2\end{cases}
$$

where $a=1$ if $\boldsymbol{b}$ adopts $\lambda^{b}{ }_{1}$, otherwise $\boldsymbol{b}$ adopts $\lambda^{b}{ }_{2}$ Since $T_{1}$ (respectively, $T_{2}$ ) is the number of rounds for $\boldsymbol{b}$ adopting $\lambda^{b}{ }_{1}$ (respectively, $\lambda^{b}{ }_{2}$ ) to reach an agreement with $\boldsymbol{s}$, it follows that $t \rightarrow T_{1}$ iff $k_{1, t} \rightarrow 0$ and $t \rightarrow T_{2}$ iff $k_{2, t} \rightarrow 0$. Since the initial spreads for both strategies $\lambda^{b}{ }_{1}$ and $\lambda^{b}{ }_{2}$ is $k_{1,0}=k_{2,0}$, and for all $i,\left[1-\left(\frac{2 i+1}{\tau^{b}}\right)^{\lambda_{1}^{b}}\right]>\left[1-\left(\frac{2 i+1}{\tau^{b}}\right)^{\lambda_{2}}\right]$, it follows that:

$$
\begin{equation*}
\text { For all } t>0, k_{1, t}>k_{2, t} \tag{6}
\end{equation*}
$$

Consequently, at round $t$, if $k_{1, t} \rightarrow 0$, then $t \rightarrow T_{1}$ and $k_{2, t} \rightarrow 0$. But, $k_{2, t} \rightarrow 0$ does not imply $k_{1, t} \rightarrow 0$. Hence, it follows that $T_{1}>T_{2}$, and $\boldsymbol{b}$ adopting a strategy with $\lambda^{b}{ }_{1}$ requires more negotiation rounds to reach an agreement with $s$ than when it adopts a strategy with $\lambda^{b}{ }_{2}$.

Lemma 3.2: The conservative strategy $\left(\lambda^{b}{ }_{1}>1\right)$ is the optimal strategy for a market-driven agent $\boldsymbol{b}$ regardless of the strategy that its trading partner $\boldsymbol{s}$ adopts.

Proof: Let $T_{1}$ (respectively, $T_{2}$ ) be the number of rounds that $\boldsymbol{b}$ adopting $\lambda^{b}{ }_{1}>1$ (respectively, $\lambda^{b} \leq 1$ ) reaches an agreement with $\boldsymbol{s}$. Without loss of generality, assume that $\boldsymbol{b}$ makes concession first. From lemma 3.1, it follows that $T_{1}>T_{2}$, hence, at $T_{2}$, there are two possible cases:

1) $T_{2}=2 I+1$ : For offer $l^{s} T_{2}$ sent by $\boldsymbol{s}$ in round $T_{2}$ :

$$
\begin{array}{ll}
l^{s \rightarrow b_{1}}=l_{2} s-\sum_{i=1}^{I}\left(k_{1,2 i}\right)\left(\frac{2 i}{\tau^{s}}\right)^{\lambda^{s}} & \text { if } \boldsymbol{b} \text { adopts } \lambda^{b}{ }_{1} \\
l^{s \rightarrow b_{2}}=l_{T_{2}}^{s}{ }_{0}-\sum_{i=1}^{I}\left(k_{2,2 i}\right)\left(\frac{2 i}{\tau^{s}}\right)^{\lambda^{s}} & \text { if } \boldsymbol{b} \text { adopts } \lambda^{b}{ }_{2}
\end{array}
$$

From (6) in lemma 3.1, for $t>0, k_{1, t}>k_{2, t}$, hence, it follows that $k_{1, T_{2}}>k_{2, T_{2}}$ and $l^{s \rightarrow b_{1}} T_{2}<l^{s \rightarrow b_{2}} T_{2}$. Since at $T_{2}, \boldsymbol{b}$ adopting $\lambda^{b}$ reaches an agreement with $\boldsymbol{s}$, $l^{s \rightarrow b_{2}} T_{2}=l^{b_{2} \rightarrow s} T_{2}$. Since $T_{1}>T_{2}, \boldsymbol{s}$ and $\boldsymbol{b}$ adopting $\lambda^{b}{ }_{l}$ will continue to make concession from $t>T_{2}$ until $t<T_{1}$. Hence, it follows that $l^{s \rightarrow b_{1}} T_{1}<l^{s \rightarrow b_{1}} T_{2}$. At $T_{1}$ when $\boldsymbol{s}$ and $\boldsymbol{b}$ adopting $\lambda^{b}{ }_{1}$ reach an agreement, $l^{b_{1} \rightarrow s}{ }_{T_{1}}=l^{s \rightarrow b_{1}}{ }_{T_{1}}$. Consequently, it follows that $l^{b_{1} \rightarrow s} T_{T_{1}}=l^{s \rightarrow b_{1}} T_{1}<l^{s \rightarrow b_{1}} T_{2}<l^{s \rightarrow b_{2}} T_{2}=l^{b_{2} \rightarrow s} T_{2} . \quad$ Hence, $v_{b}\left(l^{b_{1} \rightarrow s}{ }_{T_{1}}\right)>v_{b}\left(l^{b_{2} \rightarrow s}{ }_{T_{2}}\right)$, where $v_{b}$ is a function that generates the utilities of the proposals $l^{b_{1} \rightarrow s}{ }_{T_{2}}$ and $l^{b_{2} \rightarrow s}{ }_{T_{2}}$.
2) $T_{2}=2 I+2$ : For offer $l^{s} T_{2}$ sent by $s$ in round $T_{2}$

$$
\begin{array}{ll}
l^{s \rightarrow b_{1}} T_{2}=l^{s}{ }_{0}-\sum_{i=1}^{I+1}\left(k_{1,2 i}\right)\left(\frac{2 i}{\tau^{s}}\right)^{x i} & \text { if } \boldsymbol{b} \text { adopts } \lambda^{b}{ }_{1} \\
l^{s \rightarrow b_{2}} T_{2}=l^{s}{ }_{0}-\sum_{i=1}^{I+1}\left(k_{2,2 i}\right)\left(\frac{2 i}{\tau^{s}}\right)^{x i} & \text { if } \boldsymbol{b} \text { adopts } \lambda^{b}
\end{array}
$$

The proof that $v_{b}\left(l^{b_{1} \rightarrow s}{ }_{T_{1}}\right)>v_{b}\left(l^{b_{2} \rightarrow s}{ }_{T_{2}}\right)$ for case (2) is analogous to case (1) and is omitted due to space limitation. Since $v_{b}\left(l^{b_{1} \rightarrow s}{ }_{T_{1}}\right)>v_{b}\left(l^{b_{2} \rightarrow s}{ }_{T_{2}}\right)$ for cases (1) and (2), the conservative strategy is the optimal strategy for $\boldsymbol{b}$ regardless of the strategy that $\boldsymbol{s}$ chooses -

Sequential equilibrium: In analyzing the mutual strategic behaviors of market-driven agents, negotiation is viewed as a game $\Gamma$ of incomplete information. In $\Gamma$, an $M D A$ has imperfect information about the deadline and strategy of its trading partner. Since MDAs are imperfectly informed, the idea of sequential equilibrium [12, p95] is used to demonstrate that their strategies are in equilibrium [12, p41]. The notion of sequential equilibrium requires the specifications of: a strategy profile $\pi$ and a belief system $\mu$. Let $\pi$ $=\left(S^{b}, S^{s}\right)$ such that $S^{b}$, and $S^{s}$ are the strategies of buyer $\boldsymbol{b}$ and seller $\boldsymbol{s} . \mu$ is a function that assigns a probability $\mu(h) \in[0,1]$ to each decision node $h$ in $\Gamma$ such that $\sum_{h \in I} u(h)=1$ for all information sets $\boldsymbol{I}$. For instance, at $t=1$ in Fig. $1, h_{2}, h_{3}$, and $h_{4}$ form the information set $I_{1}$ of $\boldsymbol{s}$, and $\mu\left(h_{2}\right)+\mu\left(h_{3}\right)+\mu\left(h_{4}\right)=1$. $\mu$ represents an $M D A$ 's belief about the history of negotiation.

Definition 3: A sequential equilibrium of $\Gamma$ is a pair $(\pi, \mu)$ that satisfies the following:
(i) Sequential rationality: At each information set $I$ of each agent $a_{i}$, the strategy of $a_{i}$ is the best response to other agents' strategies (ie, optimal), given $a_{i}$ 's beliefs in $I$.
(ii) Consistency: At each information set $I, a_{i}$ updates its beliefs based on strategy profile $\pi$ using Bayes rules.

By Bayes rules, at $I$, the probability of reaching a decision node $h_{i}$ according to $\pi$ is $\frac{P\left(h_{i}, \pi\right)}{\sum P}$ where $P\left(h_{i}, \pi\right)$ and $P(h, \pi)$ denote the probabilities of reaching $h_{i}$ and $h$ $\sum_{h \in I} P(h, \pi)$
respectively according to $\pi$. For instance, at $I_{1}$, if $\boldsymbol{b}$ chooses $B_{1}, B_{2}$, and $B_{3}$ with probabilities $p_{2}, p_{3}$, and $p_{4}$ respectively, then $\boldsymbol{s}$ must assign probabilities $p_{2}$,
$\qquad$ $\frac{p_{3}}{p_{2}+p_{3}+p_{4}}$ and $\frac{p_{4}}{p_{2}+p_{3}+p_{4}}$ of reaching $h_{2}, h_{3}$, and $h_{4}$ respectively.

Proposition 3: There exists a unique sequential equilibrium of $\Gamma$.
Proof: In $\Gamma$, buyer $\boldsymbol{b}$ and seller $\boldsymbol{s}$ send proposals alternately. Assume without loss of generality that $\boldsymbol{b}$ sends its proposal first. At $t=0$, buyer $\boldsymbol{b}$ starts the negotiation by choosing its optimal strategy $B_{l}$ (lemma 3.2), and the game proceeds to $t=1$. At $t=1, s$ is unaware of the strategy that $\boldsymbol{b}$ adopts, hence, at information set $I_{1}, \boldsymbol{s}$ does not know whether play reaches $h_{2}, h_{3}$, or $h_{4}$. However, regardless of $\boldsymbol{s}$ 's belief about the history of negotiation, i.e. whether $h_{2}, h_{3}$, or $h_{4}$ is reached, $\boldsymbol{s}$ will choose $S_{I}$ because by lemma 3.2, $S_{I}$ is the optimal strategy for $\boldsymbol{s}$ at $I_{1}$ regardless of the strategy that $\boldsymbol{b}$ chooses at $t=0$. At $t=2$, even though $\boldsymbol{b}$ does know which strategy $\boldsymbol{s}$ adopts, $\boldsymbol{b}$ knows that $I_{2}$ is reached with (C) 2003 ACM
probability of 1 , because at $t=0, \boldsymbol{b}$ chooses $B_{l}$. From lemma 3.2, $B_{l}$ is also the optimal strategy for $\boldsymbol{b}$ at $I_{2}$. Iterating the arguments at $t=0, t=1$ and $t=2$, at every information set that is $\boldsymbol{b}$ 's turn to move, the optimal strategy for $\boldsymbol{b}$ is $B_{l}$, and at every information set that is $\boldsymbol{s}$ 's turn to move, the optimal strategy for $\boldsymbol{s}$ is $S_{l}$. Consequently, the strategy profile $\pi=\left(B_{l}, S_{l}\right)$ satisfies the requirement for sequential rationality. Furthermore, both $\boldsymbol{b}$ and $\boldsymbol{s}$ adhere to $\left(B_{l}, S_{I}\right)$ regardless of their beliefs about the negotiation histories. Hence, $\left(B_{l}, S_{I}\right)$ is a sequential equilibrium of $\Gamma$. In addition, the sequential equilibrium at $\left(B_{l}, S_{l}\right)$ is also unique because $B_{I}$ and $S_{l}$ are the optimal strategies of $\boldsymbol{b}$ and $\boldsymbol{s}$ at every of their information sets, and there do not exist any other equilibrium where either $\boldsymbol{b}$ or $\boldsymbol{s}$ deviates from its optimal strategy .

## 5. DISCUSSION AND CONCLUSION

Propositions 1 and 2 further elaborate and support the claim previously made in [3] that $M D A s$ are designed to avoid making excessive concessions in favorable markets or to make inadequate compromises in unfavorable markets. Consequently, with respect to market opportunity and competition, an $M D A$ does not have the incentive of making any other amounts of concession other than $\Delta k_{\text {opp }}$ and $\Delta k_{\text {com }}$. Proposition 3 shows that the time-dependent strategies of $M D A s$ are in equilibrium. In [10], $(\tau, \varepsilon)$ forms the timedependent strategy of an $M D A$. Hence, $M D A s$ with different $\varepsilon$ adopts different (conservative) strategies in making concession. From a negotiator's perspective, one resists time pressure by adjusting one's level of aspiration to what is believed to be optimal within the available time [13]. In [10], the amount of concession $\Delta k_{D L}$ made by an $M D A$ with respect to deadline is based on $\varepsilon$ and regardless of the strategy adopted by its trading partner. Consequently, the strategies of $M D A s$ are in equilibrium because with respect to opportunity, competition and deadline, every $M D A$ does not find any incentive to deviate from making $\Delta k_{o p p}, \Delta k_{c o m}$ and $\Delta k_{D L}$ respectively. Theoretical results from this work show that MDAs are stable (and are designed to behave in the desired manner). In addition to showing the desirable property of stability, which is one of the essential evaluation criteria for automated negotiation systems [11, p21], this work also supplements and complements the empirical results obtained from previous work on $M D A s[6,10]$. Both theoretical results from this work, as well as empirical results previously obtained from $[6,10]$ collectively show that $M D A s$ are stable, and achieve relatively high utility and success rates. While this work (in its present stage) assumes that all negotiating parties are $M D A s$, future work will explore analyses of negotiation between $M D A s$ and agents adopting other strategies.
